## 1 Factor analysis

### 1.1 Linear factor analysis

We denote the observed data as  $x$ , the latent factor as  $y$  and the error as  $\epsilon$ . Suppose  $y \sim \mathcal{N}(\mu, \Lambda)$ ,  $\epsilon \sim \mathcal{N}(0, \sigma^2 I)$ ,  $E(y\epsilon^T) = 0$ , where  $A$  is an  $n \times m$  matrix,  $n$  is the dimension of  $x$ ,  $m$  is the dimension of  $y$  and  $m < n$ . Please explain why there is more than one solution that satisfy  $E(xx^T) = A\Lambda A^T + \Sigma$ . When  $\Sigma$  is not a general positive definite matrix, but a diagonal matrix, how many solution exists? And if  $\Sigma = \sigma^2 I$ , how many solution exists?

answer

### 1.2 Binary factor analysis

If  $y$  is a latent factor where each dimension is an independent variable that subjects to a different Bernoulli distribution, what are the answers to the above three questions?

The answer

## 2 Projection

### 2.1 Orthogonal projection

Suppose we have a hyperplane whose orthogonal basis are  $\alpha_1, \alpha_2, \dots, \alpha_k, k < n$ . Now we have a  $n$ -dimensional vector  $x$  and we want to apply an orthogonal projection on the hyperplane. Please compute the corresponding projection matrix  $P$ .

Define  $u = [\alpha_1, \alpha_2, \dots, \alpha_k, 0 \times (n - k)]^T$ , then  $P = uu^T$  is the corresponding projection matrix.

Easy to prove that  $P^2 = P$ , then  $P$  is a projection matrix; Since  $P$  is self-adjoint, the projection is orthogonal.

## 3 Clustering

### 3.1 Comparison between Gaussian mixture model and k-means

Please add constraints to Gaussian mixture model so that it degenerates into k-means algorithm.

Given a training set  $x^{(1)}, \dots, x^{(m)}$ .

K-means:

1. Initialize cluster centroids  $\mu_1, \mu_2, \dots, \mu_k \in R^n$
2. Repeat :
  - (a) For every  $i$ , set  $c^{(i)} := \operatorname{argmin} \|x^{(i)} - \mu_j\|$
  - (b) For every  $j$ , set  $\mu_j := \frac{\sum_{i=1}^m 1\{c^{(i)}=j\}x^{(i)}}{\sum_{i=1}^m 1\{c^{(i)}=j\}}$

EM Algorithm for Gaussian mixture model (GMM):

1. For each  $i, j$ , set  $w_i^{(j)} := p(z^{(i)}=j|x^{(i)}; \phi, \mu, \Sigma)$
2. M-step : Update the parameters  $\phi, \mu, \Sigma$

We find that GMM is reminiscent of the K-means clustering algorithm, except that instead of the "hard" cluster assignments  $c(i)$  (assign a point to a cluster centroid), we instead have the "soft" assignments  $w_j^{(i)}$  (calculate the possibility that a point belongs to each separated Gaussian model). To make these two processes the same :

1. All the single Gaussian models have the same variance  $\sigma$ , such that the maximum possibility that a point belongs to a single Gaussian model depends only on the distance  $x^{(i)} - \mu_j$ , which is the same as in K-means ;
2. The variance  $\sigma$  tends to be 0, such that  $w_i^{(j)}$  tends to have only two values 0, 1, the "soft" assignment becomes a "hard" assignment. (This condition covers the first condition)

## 4 Optional summary work

Please compare PCA, FA and ICA.

PCA: Principal Components Analysis project the variables to a lower dimension basis by eigenvector calculation to remove the redundancy.

FA: Factor Analysis is based on a probabilistic model. In a FA model, we imagine that each datapoint is generated by sampling a low dimension multivariate Gaussian and then map it to a high dimension multivariate Gaussian by a linear transform with a noise. The transform of dimension solves the problem that the training set size is significantly smaller than the dimension of the data.

ICA: Independent Components Analysis will also find a new basis in which to represent the data, but the goal is to separate the independent components by finding the mixing matrix.
